1 Genotype Likelihoods from Reads

$$\begin{split} L(g=1) &= p(d \,|\, g=1) \\ &= p(d,g=ra \,|\, g=1) + p(d,g=rb \,|\, g=1) + p(d,g=rc \,|\, g=1) \\ &= \sum_{g} p(d \,|\, g=ra) \times p(g=ra \,|\, g=1) \end{split}$$

Here we do not favour any heterozygous genotype, and all have likelihood 1/3. This may be changed to reflect empirical or dbSNP data

$$\begin{split} L(g=1) &= 1/3 \sum_a p(d \mid g=ra) \\ &= 1/3 \sum_a p(d \mid g=ra, \text{ado}) \times p(\text{ado}) + p(d \mid g=ra, \text{no ado}) (1-p(\text{ado})) \\ p(d \mid g=ra, ado) &= p(d \mid g=ra, dropr) * p(dropr) + p(d \mid g=ra, dropa) * p(dropa) \end{split}$$

Here we assume either allele is equally likely to be dropped in an ado event and p(drop r) = p(drop a) = 0.5. This is unlikely to change.

$$p(d \mid g = ra, ado, drop a) = \prod_{i} p(d_i \mid g = rr)$$

 $p(d \mid g = ra, ado, drop r) = \prod_{i} p(d_i \mid g = aa)$

2 Cell-locus Posterior probabilities

Using Bayes' rule:

$$p(g = k \mid d) = \frac{p(d \mid g = k) p(g = k)}{p(d)}$$

For a cell at a given locus p(d) will be constant, therefore instead of finding it we can simply normalise:

$$p(g = k \mid d) = \frac{\tilde{p}(g = k \mid d)}{\sum_{l} \tilde{p}(g = l \mid d)}$$
